

Waiting increases re-collision with a dispatch-time baseline

First-order $q = 1 - \exp(-\mu E)$: $E = \delta + R$ at dispatch; $E \approx R$ when re-reading. Fixed $R = 0.25$.

Completed attempts are selected by the serial queue and cutoff; these curves do not establish an independent-attempt law.

Ratio intervals are not identified by the aggregate inputs. The dotted vertical line marks $1/\mu$, not a threshold.
